METHOD OF OBTAINING AN IMAGE

The present invention relates to a method of obtaining an image and, more particularly, a method of obtaining a substantially linear representation of the brightness of an image having a wide dynamic range.

Digital electronic cameras and other similar imaging devices and systems often use CCD (charge-coupled device) sensors, and work by converting incident photons into charge and accumulating the charge in each pixel for the duration of the exposure. Like all other imaging devices, including conventional wet photography and other digital systems, such imaging devices impose limits on the dynamic range of the signal they can capture. In particular, image details in the regions which are either too dark or too bright cannot be captured. In such digital devices, the charge in each cell on to which part of an image is imposed, is read out and converted into a number representing its intensity or brightness via an analogue-to-digital converter. Therefore, if the image is too bright, or the exposure time is too long, then saturation occurs and the brightness of the image is clipped to the maximum representable intensity and no detailed information is available in these areas. This imposes an upper limit on the detected brightness. Conversely, if the image is too dark any signal is indistinguishable above the quantisation noise in the analogue to digital converter and therefore detail is lost in these dark areas.

An important characteristic of this clipping process is that it is destructive and destroys information which cannot subsequently be recovered from the recorded image. Therefore any attempt to capture the information that would otherwise be missing, must be made at the time of capture of the image. The resulting image requires a wider dynamic range than that of the basic sensor and analogue-to-digital converter. It is possible, then, to correct overall over- or under-exposure by adjusting the time over which the sensor is accumulating charge so that the full dynamic range of the digital imaging system is utilised. However, whilst this uses the available dynamic range to best effect, it cannot assist where there are both very bright and very dark regions, for example, in an electrophoresis gel, in the same field of view as both lengthening and reducing the exposure time cannot be carried out simultaneously. In these circumstances

it is possible to capture either the bright areas or the dark areas accurately, but not both simultaneously.

Now, it is evident that, under such circumstances, a series of images captured using different exposure times will contain all of the available information. Indeed a technique well known in the art involves simply averaging together a series of images recorded with steadily increasing exposure times. This can be shown to result in an image which is approximately proportional to the logarithm of the intensity. Such a result may be pleasing to the eye in that very bright regions do not suppress the detail of very dark regions, but such images lack the crucial linear quality often required for quantitative analysis.

It is possible to obtain camera systems having an inherent high dynamic range and whose output can be digitised to a 16-bit resolution. Such systems can achieve the dynamic range necessary to image both very dark and very light areas without saturation, but they are both very expensive and generally slow to operate with regard to focussing and adjusting the field of view. The advantages of the present invention are that an inexpensive sensor and digitizer may be used, and the readout can be rapid, facilitating convenient, fluid adjustment of focus.

The ideal digital output v'_{xy} from an analogue-to-digital converter of a true image of intensity i_{xy} is given by

$$v'_{xy} = KTi_{xy} + C$$

where T is the exposure time, K is the overall gain of the system, and C is an offset. However, due to the saturation at the high and low ends of the range the true output v_{xy} is constrained by:

$$v_{xy} = \begin{cases} KTi_{xy} + C & v_{\min} < v'_{xy} < v_{\max} \\ v_{\max} & \text{when } v'_{xy} \geq v_{\max} \\ v_{\min} & v'_{xy} \leq v_{\min} \end{cases}$$

In order to reduce the effects of noise an average over a series of images with different exposure times T_n can be taken, giving a superior estimate of the true image i_{xy} :

$$\hat{i}_{xy} = \frac{1}{n} \sum_n \left(\frac{v_{n,xy} - C}{KT_n} \right)$$

Averaging of this kind is well known in the art but it does not resolve the problem of saturated areas and dark areas and therefore the present invention discards the values for these pixels from the average, such that only pixels having significant values, that is those well away from the dark and light limits, are considered when averaging the images together.

The present invention is aimed at overcoming the shortcomings of the prior art methods.

According to the present invention there is provided a method of creating an image which includes the steps of:

obtaining a substantially linear representation of the brightness of an image, the method comprising, for each of a set of pixels (x, y) in a two dimensional array, calculating an estimate of the true image intensity (\hat{i}_{xy}) as a weighted average of n samples of the apparent image intensity ($v_{n,xy}$) as

$$\hat{i}_{xy} = \frac{\sum_n \left(w_{n,xy} \left(\frac{v_{n,xy} - C}{KT_n} \right) \right)}{\sum_n w_{n,xy}} = \frac{1}{K} \frac{\sum_n \left(w_{n,xy} \left(\frac{v_{n,xy} - C}{T_n} \right) \right)}{\sum_n w_{n,xy}}$$

where $v_{n,xy}$ is the apparent intensity measured, T_n is the exposure time, K is the gain of the system, C is an offset and $w_{n,xy}$ is a weighting factor which is defined to maximise the signal-to-noise ratio and discard insignificant, that is saturated or near zero, values;

thereafter saving each of the values \hat{i}_{xy} together with other data representing the image; and

outputting the image to a display or to a printing device or to a subsequent analysis.

For example, in the most simplistic case:

$$w_{n,xy} = \begin{cases} 1 & v_{\min} < v_{n,xy} < v_{\max} \\ 0 & \text{when } v_{n,xy} \geq v_{\max} \\ 0 & v_{n,xy} \leq v_{\min} \end{cases}$$

5 A further example is that of Gaussian noise which is minimised, and hence the signal-to-noise ratio is maximised, when $\frac{w_{n,xy}}{KT_n} = 1$ and therefore

$$w_{n,xy} = \begin{cases} KT_n & v_{\min} < v_{n,xy} < v_{\max} \\ 0 & \text{when } v_{n,xy} \geq v_{\max} \\ 0 & v_{n,xy} \leq v_{\min} \end{cases}$$

10 The invention provides for an image to be formed over a wider dynamic range than that of the basic sensor and A-to-D converter and enables the image to be a linear representation of the brightness of the original scene whilst taking into account all the available data and with an optimal signal-to-noise ratio. It also allows an image series to be captured automatically to cover a wide range of exposure times as the number of saturated and zero output pixels is a natural
15 output from each step, so that the sequence can be chosen to cover the entire dynamic range of the specimen automatically rather than arriving, by iteration, at the optimal single exposure time for the whole specimen which is the technique currently employed in the art.

20 The choice of the exposure times T_n is very important. For practical cameras, the exposure time is subject to limits and not all exposure times are possible within those limits. As part of the implementation of the present invention, it is required to determine those pixels which are saturated. The operation of a system incorporating the invention can be broken down into three phases: adjustment, capture and analysis. By counting those pixels which are
25 saturated and those for which there is a zero output for a particular frame, the implementation can determine whether the frame is generally over- or under-exposed. During the adjustment phase, the "best" single exposure time for the

specimen is selected. This selection process is either performed manually via viewing unmodified digital image directly on screen or automatically from the frequency histogram of the intensity levels of the image.

As the exposure time is varied, the number of pixels at the limits may be monitored. If the exposure time is reduced to a point where no pixels are saturated then there is no more information to be obtained by any further reduction in exposure time. Similarly, if the exposure time is increased to the point where most pixels are saturated there is little point in any further increase. In the presence of noise, it may be worth going a little beyond each of these limits so as to increase the number of valid samples for the averaging.

This approach can be subject to two problems: sometimes the ratio between the successive exposure times is not precisely known and there is often an offset present in the camera electronics or in the analogue to digital converter which results in a further offset to each image.

In order to resolve these difficulties a regression calculation can be performed between successive pairs of images in order to determine the linear function relating them. Given this relationship, each image can be transformed to match the scale and offset of the other. For unsaturated pixels there is a linear relationship between the images recorded at different exposure times, where the gradient is the ratio of the two exposure times and the offset is a constant for all pixels.

For example if one considers:

$$v'_{m,xy} = K T_m i_{xy} + C$$

and

$$v'_{n,xy} = K T_n i_{xy} + C$$

these can be re-arranged as:

$$v'_{m,xy} = \frac{T_m}{T_n} v'_{n,xy} + C - C \frac{T_m}{T_n}$$

which is of the linear form:

$$v'_{m,xy} = a v'_{n,xy} + b$$

So, for unsaturated pixels, there is a linear relationship between the images recorded with different exposure times, where the gradient a is the ratio of the two exposure times and the offset b is a constant for all pixels. The situation is slightly complicated by the presence of noise in both the v_m and v_n images and

5 the best fit linear relationship in this case is given by a “perpendicular” regression, which minimises the sum of the squares of the perpendicular distance between a point formed by the coordinates $(v_{n1,xy}, v_{n2,xy})$ and the fitted linear relationship.

An example of an implementation of a standard perpendicular regression technique that accounts for the possibility of saturated pixels is the following

10 pseudocode:

```

    s = sL = sn = sm = snn = smm = snm = 0
    for all y values of image
    {
15         for all x values of image
            {
                (vn is intensity value of image n at x,y and vm is intensity value of image m at x,y)
                if vn > vmin AND vn < vmax AND vm > vmin AND vm < vmax
                {
20                     s = s + 1
                     sn = sn + vn
                     snn = snn + (vn*vn)
                     sm = sm + vm
                     smm = smm + (vm*vm)
25                     snm = snm (vn*vm)
                }
                else
                {
30                     sL = sL + 1
                }
            }
        }
    }

```

$$sdndndmdm = snn - (sn * sn / s) - snm + (sm * sm / s)$$

$$sdndm = snm - (sn * sm / s)$$

$$aa = sdndndmdm / sdndm$$

$$5 \quad a = (-aa + \text{SquareRoot}(aa * aa + 4)) / 2$$

$$b = (sm - a * sn) / s$$

10 In this way the linear relationship between one image and another may be determined. This is best done between one image and the next in the series, because, in this way, the number of spatial locations (x,y) whose intensity is not saturated in either image, is maximised, resulting in the best statistics and the most accurate estimate of a and b .

As a by-product, sL is the number of pixels which is saturated in at least one of the images.

15 Having determined a and b , each image can be transformed to match the scale and offset of the first in the series. The expression for the averaging kernel is then:

$$20 \quad \hat{i}_{xy} = \frac{\sum \left(w_{n,xy} \left(\frac{v_{n,xy} - \sum_n b_n}{\prod_n a_n} \right) \right)}{\sum_n w_{n,xy}}$$

where a_n and b_n are the gradient a and offset b measured between image n and image $n-1$ ($a_1 = 1$; $b_1 = 0$), where:

25

$$w_{n,xy} = \begin{cases} a_n & v_{\min} < v_{n,xy} < v_{\max} \\ 0 & \text{when } v_{n,xy} \geq v_{\max} \\ 0 & v_{n,xy} \leq v_{\min} \end{cases}$$

30

One example of a system constructed in accordance with the present invention will now be described with reference to the accompanying drawing, in which:

Figure 1 is a general view of the apparatus.

The system as implemented in the example includes a camera 1 (in the particular example, a JVC KY-F50E camera). The camera 1 output signals are digitized by analogue to digital converters which form part of a framestore board 2 (a Synoptics Prysm framestore) fitted within a personal computer 3 (a Gateway 2000 PC with a 500 MHz Pentium II processor and 256 MB RAM running Windows 98) and then the digital image 4 is placed in the computer's memory and may be displayed on a monitor 5.

Thereafter the brightness values \hat{i}_{xy} for each pixel are calculated in accordance with the expressions above.

Control of the system was achieved using software written in Visual Basic and C++ using Synoptics Image Objects to handle the display and processing functions.

In operation, firstly, during the adjustment phase the "best" single exposure time for the specimen object is selected. This selection process can either be performed via the system displaying on screen the unmodified digital image direct from the camera 1 and allowing the user to select an exposure time which is reasonably rapid yet long enough that sufficient of the contrast in the specimen can be seen or the exposure time may be determined automatically from the frequency histogram of the intensity levels of the image.

Thereafter, during the capture phase a number of steps are under taken according to the present invention. First, areas of computer memory are located for the values needed during the process corresponding to:

25

$$\sum_n \left(w_{n,xy} \left(\frac{v_{n,xy} - \sum_n b_n}{\prod_n a_n} \right) \right) \text{ and } \sum_n w_{n,xy}$$

30

The data in these memory areas is stored in high precision format in order to avoid data degradation due to rounding or truncation.

The exposure time selected during the adjustment phase is then used as a starting point. An image is acquired using this exposure time. For this image,

a is taken as 1 and b as zero, w is 1 for those pixels having an "in range" value and zero otherwise, and the summations identified above are initialised with the values indicated. The exposure time is then increased by approximately a factor of 2, and another image acquired.

5 For each new image the following processes are carried out:

- the image is compared to the previous one acquired to determine the linear relationship between the gradient a and offset b, considering only those spacial pixel locations in which the intensities in both images are well away from the limits v_{min} and v_{max} ;

10 • the product of all the a values, and a sum of all the b values, is computed;

- for each pixel location in which the new image of intensity value is within range, the values in the two formations given above are updated; (w is equal to the product of all the a values for those pixels having an "in range" value, and zero otherwise)

15

- if the number of spatial locations for which the new image's intensity value exceeds v_{max} is greater than a predetermined percentage of all spatial locations in the image, then there is little point in increasing the exposure time further.

20 This process can be repeated to resume for the same starting exposure time but decrease in the exposure time for each iteration until more than a given percentage of the spatial locations have an intensity less than v_{min} . Finally, the ratio of the two accumulation values is calculated to form a result image. This image may be subject to a linear rescaling or offset to make it suitable for

25 conversion to a fixed point format image for further processing.

CLAIMS

1. A method of creating an image which includes the steps of:

obtaining a substantially linear representation of the brightness of an
 5 image, the method comprising, for each of a set of pixels (x, y) in a two
 dimensional array, calculating an estimate of the true image intensity (i_{xy}) as a
 weighted average of n samples of the apparent image intensity $(v_{n,xy})$ as

$$10 \quad \hat{i}_{xy} = \frac{\sum_n \left(w_{n,xy} \left(\frac{v_{n,xy} - C}{KT_n} \right) \right)}{\sum_n w_{n,xy}} = \frac{1}{K} \frac{\sum_n \left(w_{n,xy} \left(\frac{v_{n,xy} - C}{T_n} \right) \right)}{\sum_n w_{n,xy}}$$

where $v_{n,xy}$ is the apparent intensity measured, T_n is the exposure time, K is the
 gain of the system, C is an offset and $w_{n,xy}$ is a weighting factor which is defined
 15 to maximise the signal-to-noise ratio and discard insignificant, that is saturated
 or near zero, values;

thereafter saving each of the values \hat{i}_{xy} together with other data
 representing the image; and
 outputting the image to a display or to a printing device.

20 2. A method according to claim 1, wherein a linear relationship is established
 between images recorded with different exposure times by the use of a
 perpendicular regression technique whereby each image is transformed to match
 the scale and offset of the first in the series and whereby the weighted average
 25 is calculated as:

$$30 \quad \hat{i}_{xy} = \frac{\sum_n w_{n,xy} \left(\frac{v_{n,xy} - \sum_n b_n}{\prod_n a_n} \right)}{\sum_n w_{n,xy}}$$

where a_n and b_n are the gradient a and offset b measured between image n and image $n-1$ ($a_1 = 1$; $b_1 = 0$) when

5

$$w_{n,xv} = \begin{cases} \prod_n a_n & v_{\min} < v_{n,xv} < v_{\max} \\ 0 & \text{when } v_{n,xv} \geq v_{\max} \\ 0 & v_{n,xv} \leq v_{\min} \end{cases}$$

METHOD OF OBTAINING AN IMAGE

ABSTRACT

5 A method of creating an image 4 obtained from say a camera 1 to obtain a substantially linear representation of the brightness of the image includes, for each of a set of pixels (x, y) in a two dimensional array, calculating, in a computer 3, an estimate of the true image intensity (i_{xy}) as a weighted average of n samples of the apparent image intensity $(v_{n,xy})$. This is calculated as:

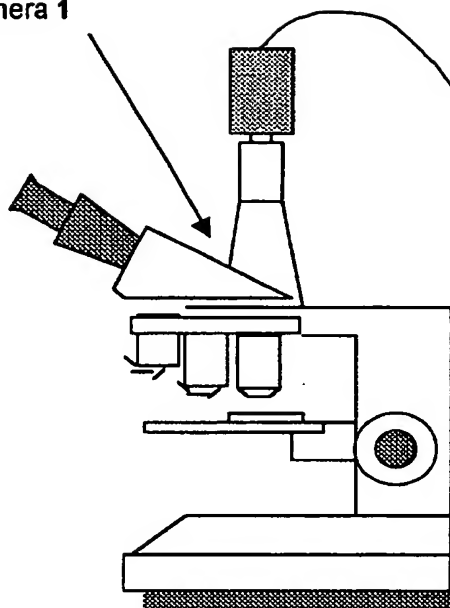

10

$$\hat{i}_{xy} = \frac{\sum_n \left(w_{n,xy} \left(\frac{v_{n,xy} - C}{K T_n} \right) \right)}{\sum_n w_{n,xy}} = \frac{1}{K} \frac{\sum_n \left(w_{n,xy} \left(\frac{v_{n,xy} - C}{T_n} \right) \right)}{\sum_n w_{n,xy}}$$

15 where $v_{n,xy}$ is the apparent intensity measured, T_n is the exposure time, K is the gain of the system, C is an offset and $w_{n,xy}$ is a weighting factor which is defined to maximise the signal-to-noise ratio and discard insignificant, that is saturated or near zero, values. Thereafter each of the values \hat{i}_{xy} is saved together with other data representing the image 4, before the image is output to a display 5 or
20 to a printing device.
